

First Chart Story: Turning Numbers into a Narrative

Data Analytics Track — Veda Technology Internship

Submitted by: Akshat Srivastava

Dataset: Iris (150 flowers, 3 species — setosa, versicolor, virginica)

1. Which species has the largest petals?

Takeaway: *Virginica has by far the largest average petal length (5.55 cm), more than 3.5x setosa's (1.46 cm).*

2. What is the species composition of the dataset?

Takeaway: The dataset is perfectly balanced — each species makes up exactly 33% (50 flowers) of the 150 samples.

3. How do average measurements change across species?

Takeaway: Petal length and petal width rise sharply from setosa to virginica, while sepal width stays nearly flat — petals separate the species far better than sepals.

4. Which measurement varies the most across species?

Takeaway: Petal length has the widest range (4.09 cm) across species, making it the single most discriminating feature; sepal width barely varies (0.66 cm).

Summary

This dataset has 150 flowers, equally split between three Iris species — setosa, versicolor, and virginica (50 each). Looking at the four charts together, one clear pattern emerges: **petal size is what separates the species, not sepal size**. Virginica has the biggest petals on average, followed by versicolor, then setosa. When we track all four measurements across species, petal length and petal width both grow steadily and sharply, while sepal length and sepal width barely change. This is confirmed by the range chart too — petal length varies the most (4.09 cm) across species, making it the single best measurement to look at if you want to tell the three species apart.
